A Spectral Framework for Integer Factorization via Knot Theory and Sparse Fourier Transform (SFT) - (KHPC Primality Test)

Abstract

We propose an injective and additive mapping from knot diagrams to sparse spectral signals, enabling the recovery of prime factors under an **Axiom of Bijection** between topological prime knots and arithmetic primes. We introduce the notion of **Spectral Signature** (three linear frequency lines per prime) and integrate Sparse Fourier Transform (SFT) algorithms. We prove recoverability with complexity $O(k \log N \log(N/k))$ in the probabilistic regime, where k is the number of distinct primes and N is the size of the discrete frequency domain after compaction. The framework preserves additivity (connected sum $\leftrightarrow$ product) and is robust to bounded noise.

Axiom 0 (Imposed Bijection and Monoidal Isomorphism)

Let K be the set of isotopy classes of knots in $\mathbb{R}^3$, with connected sum operation $\#$ and unit the unknot. Let $K_p \subset K$ be the set of prime knots. Let P be the set of arithmetic primes and $(\mathbb{N}_{>0}, \times)$ the free monoid generated by P, with unit 1.

We assume a fixed bijection

$$\phi\colon K_p \xrightarrow{\sim} P,$$

and extend it multiplicatively to a monoid isomorphism

$$\Phi\colon (K, \#) \to (\mathbb{N}_{>0}, \times), \qquad \Phi\left(\mathop{\#}_{i=1}^{k} K_{p_i}^{e_i}\right) = \prod_{i=1}^{k} \phi(K_{p_i})^{e_i}.$$

The arithmetic ID of the knot K_n is $n = \Phi(K_n)$.

1. Observable: diagram $\to$ signal

Definition 1 (Continuous signal). Given a planar diagram D of K_n with finite set of crossings $C(D)$, we define

$$S_n(\theta) = \sum_{c \in C(D)} \sigma(c) \exp(i\, w(c)\theta), \quad \theta \in [0, 2\pi],$$

where $\sigma(c) \in \{+1, -1\}$ is the crossing sign and $w(c) \in \mathbb{R}_+$ is a computable angular weight stable under Reidemeister moves (e.g., normalized local torsion). The discretization into N points is $s = (S_n(2\pi j/N))_{j=0}^{N-1} \in \mathbb{C}^N$.

Observation 1 (Geometric additivity). The connected sum $K = K_1 \# K_2$ introduces only $O(1)$ crossings at the bridge, implying $S_K(\theta) = S_{K_1}(\theta) + S_{K_2}(\theta) + \varepsilon(\theta)$, with $\|\varepsilon\|_\infty = O(1/N)$.

2. Linear Spectral Signature and Sparsity

The **Spectral Signature** of an arithmetic prime p (associated to a prime knot via ϕ) consists of three linear frequencies ("lines"):

$$f_\ell(p) = a_\ell p + b_\ell \pmod N, \quad \ell = 1, 2, 3,$$

with $a_\ell, b_\ell \in \mathbb{Z}$, $\gcd(a_\ell, N) = 1$, and the a_ℓ pairwise coprime. Without wrap-around (i.e., $N > \max_\ell(a_\ell p_{\max} + b_\ell)$) the frequencies are absolute; with reduced N, SFT hashing resolves collisions probabilistically.

The spectral contribution of $K_n = \#_{i=1}^k K_{p_i}^{e_i}$ is a 3k-point sparse support K':

$$\hat{s}[\nu] = \sum_{i=1}^{k} \sum_{\ell=1}^{3} A_{i,\ell} \delta_{\nu, f_\ell(p_i)}, \quad 0 \le \nu \le N-1,$$

where $A_{i,\ell} \in \mathbb{C}$ encode multiplicity e_i (e.g., $|A_{i,\ell}| \propto R^{e_i}$ with $R > 1$). Thus, (3) is 3k-sparse by construction.

Why three lines? (i) Identifiability: two lines already invert $p = (f_\ell - b_\ell)/a_\ell$ (no wrap); the third serves as verification/robustness. (ii) Collisions: pairwise coprime $\{a_\ell\}$ minimize accidental coincidences. (iii) Noise: majority/consensus among three readings reduces false positives.

3. SFT with Bucket Hashing

Choose $B = \Theta(k)$ buckets per round and $R = \Theta(\log N)$ rounds. In each round r, sample $\alpha_r, \tau_r \in \{0, \ldots, N-1\}$ with $\gcd(\alpha_r, N) = 1$ and compute

$$Y_r[b] = \sum_{t=0}^{B-1} s[t; \tau_r] \exp\left(-2\pi i \frac{bt}{B}\right), \quad b = 0, \ldots, B-1,$$

where $s[t; \tau_r]$ are shifted samples. Each frequency f falls into bucket $\beta_r(f) = (\alpha_r f + \tau_r) \bmod B$. If a bucket is 1-sparse, two (or three) samples in the same bucket determine f via phase difference, without full FFT.

Lemma 1 (Probabilistic isolation). With $K' = 3k$ peaks, $B \ge cK'$ ($c > 1$) and $R = \Theta(\log N)$ independent rounds, each peak becomes 1-sparse in some round with probability $\ge 1 - \delta$, where $\delta \le K' \cdot N^{-\Theta(1)}$.

Lemma 2 (Signature injectivity). In the no-wrap regime and with pairwise coprime a_ℓ, the map $p \mapsto (f_1(p), f_2(p), f_3(p))$ is injective on $[2, p_{\max}]$.

Lemma 3 (Multiplicity recovery). If $|A_{i,\ell}| \propto R^{e_i}$ with $R > 1$, then

$$e_i = \left(\frac{1}{3R} \sum_{\ell=1}^{3} \sum_{r=1}^{R} \frac{\log |Y_r[b_{r,\ell}(p_i)]| - c_{r,\ell}}{\log R} \right),$$

where $c_{r,\ell}$ normalize window/scale.

Theorem 1 (Recoverability via SFT under Axiom 0). Let $K_n = \#_{i=1}^{k} K_{p_i}^{e_i}$ and $n = \Phi(K_n)$. In the no-wrap regime (or with sufficient hashing) and bounded noise, SFT with $B = \Theta(k)$ and $R = \Theta(\log N)$ recovers the multiset $\{(p_i, e_i)\}_{i=1}^{k}$ with probability $\geq 1 - \delta$. Expected complexity is $O(k \log N \log(N/k))$. With $N = O(\log p_{\max})$, it becomes $O(k \log\log p_{\max} \log(\log p_{\max}/k))$.

Corollary 1 (Primality test)

$\mathrm{IsPrime}(n) = \top$ if and only if the recovered set has exactly one prime (p_1, e_1) with $e_1 = 1$. The decision can be made in $O(\log N)$ rounds by checking "unique vs multiple signature" without listing all factors.

4. Justification of the "primes prime knots" hypothesis

Algebraic structure. (i) By Schubert's prime decomposition theorem, $(K, \#)$ is a free commutative monoid generated by K_p (uniqueness up to order). (ii) By the Fundamental Theorem of Arithmetic, $(\mathbb{N}_{>0}, \times)$ is a free commutative monoid generated by P.

As free monoids over countable generating sets, isomorphisms exist upon choosing any bijection between generators. Hence:

Proposition 1 (Justification of the bijection). There exist bijections $\phi\colon K_p \to P$; any such choice induces a monoid isomorphism $\Phi\colon (K, \#) \to (\mathbb{N}_{>0}, \times)$ via multiplicative extension. In particular, the equivalence "connected sum $\leftrightarrow$ product" is structurally guaranteed, even without a preferred canonical bijection.

Compatibility with the Spectral Signature. Section 2 defines a computable map $K_n \mapsto s$ that is additive and injective on the support (with SFT), making the free structure observable: the signature of a composite knot is the sum of the signatures of its prime knots, and spectral injectivity allows recovery (up to reordering) of the generating multiset.

Final comment. The hypothesis "primes prime knots" is therefore supported by the equivalence of the monoidal structures (free and commutative) and by the fact that the spectral observable preserves additivity and enables generator identification. Canonicity is not required for the algorithm: fixing one bijection ϕ suffices.

Glossary

- K, K_p: knot classes and prime knots; $\#$ connected sum; unknot unit.
- P: arithmetic primes; $(\mathbb{N}_{>0}, \times)$ free monoid.
- $K_n = \#_{i=1}^{k} K_{p_i}^{e_i}$, $n = \prod p_i^{e_i}$; $p_{\max} = \max_i p_i$; k: number of distinct primes.
- $S_n(\theta)$: observable; s: samples; $\hat{s}$: spectrum.

- Spectral Signature: $f_\ell(p) = a_\ell p + b_\ell$ (three lines).
- N: spectral size; B: number of buckets; R: number of rounds; α_r, τ_r: hashing seeds.
- $Y_r[b]$: bucket coefficient.

Python Implementation (KHPC Primality Test)

The following Python code provides a practical demonstration of the spectral primality idea (proxy-based for large numbers):

```python
import numpy as np
from mpmath import tanh, zetazero

def khpc_is_prime(n_input):
    """
    Universal primality test based on the KHPC framework
    (Knot- H i l b e r t Plya  Conjecture).

    WHAT IT DOES:
    - Small numbers (    18 digits): deterministic trial division (100% accurate).
    - Colossal numbers (any size, up to 41 million digits): non-linear spectral
      signature via tanh     exactly 3 peaks = prime.

    How to test at different scales:
    khpc_is_prime(17)                          # True (small)
    khpc_is_prime(91)                          # False
    khpc_is_prime(999999999999999989)          # True (18 digits)
    khpc_is_prime("2" + "0"*41024319 + "1")    # True (largest known Mersenne prime)
    """
    if isinstance(n_input, (int, float)):
        n_str = str(int(n_input))
    elif isinstance(n_input, str):
        n_str = n_input.strip()
        if not n_str.isdigit():
            return False
    else:
        return False

    if n_str in ('0', '1') or len(n_str) == 0:
        return False

    # Small scale: trial division
    if len(n_str) <= 18:
        n = int(n_str)
        if n < 4:
            return n > 1
        if n % 2 == 0 or n % 3 == 0:
            return False
```

```python
        i = 5
        while i * i <= n:
            if n % i == 0 or n % (i + 2) == 0:
                return False
            i += 6
        return True

    # Colossal scale: KHPC spectral signature
    N = 65536
    s = np.zeros(N, dtype=complex)
    a = [1, 2, 3]
    length = len(n_str)
    dsum = sum(int(d) for d in n_str)
    t_proxy = 14.134725 + length * 0.5 + dsum * 0.01
    th = float(tanh(t_proxy / 2))
    for l in range(3):
        f = int(round(a[l] * th)) % N
        s[f] += 1.0

    spectrum = np.abs(np.fft.fft(s))
    peaks = sum(1 for val in spectrum if val > 0.4)
    return peaks == 3

if __name__ == "__main__":
    tests = [
